Edited by Paul W. Sternberg, California Institute of Technology, Pasadena, CA, and approved March 22, 2018 (received for review September 29, 2017)

Descending signals from the brain play critical roles in controlling and modulating locomotion kinematics. In the Caenorhabditis elegans nervous system, descending AVB premotor interneurons exclusively form gap junctions with the B-type motor neurons that execute forward locomotion. We combined genetic analysis, optogenetic manipulation, calcium imaging, and computational modeling to elucidate the function of AVB→B gap junctions during forward locomotion. First, we found that some B-type motor neurons generate rhythmic activity, constituting distributed oscillators. Second, AVB premotor interneurons use their electric inputs to drive bifurcation of B-type motor neuron dynamics, triggering their transition from stationary to oscillatory activity. Third, proprioceptive couplings between neighboring B-type motor neurons entrain the frequency of body oscillators, forcing coherent bending wave propagation. Despite substantial anatomical differences between the motor circuits of C. elegans and higher model organisms, converging principles govern coordinated locomotion.

Significance

A deep understanding of the neural basis of motor behaviors must integrate neuromuscular dynamics, mechanosensory feedback, as well as local and global command signals, to predict behavioral dynamics. Here, we report on an integrative approach to define the circuit logic underlying locomotion in Caenorhabditis elegans. Our combined experimental and computational analyses revealed that (i) motor neurons in C. elegans function as oscillators; (ii) descending interneuron inputs and proprioceptive coupling between motor neurons work synergistically to facilitate the sequential activation of motor neuron activities, allowing bending waves to propagate efficiently along the body. Our work represents a key step toward an integrative view of animal locomotion.

Locomotion requires coordinated rhythmic motor activity. In both vertebrate and invertebrate motor systems, oscillatory signals that innervate muscles are generated by dedicated neurons and neural circuits with intrinsic rhythmic properties, called the central pattern generators (CPGs) (1–6). Movements, which constitute muscle activities of defined spatial pattern and temporal sequence, are driven by oscillators distributed at different body segments. Coordination of rhythmic movements requires coupling mechanisms, by which the rhythm of multiple CPGs becomes frequency- and phase-locked (5, 7).

Although the oscillatory activity of CPGs can be maintained independently of sensory inputs, proprioceptive or mechanosensitive feedbacks reshape motor dynamics during movements (8). In lamprey and leech, for example, activation of specialized proprioceptive neurons, either by current injection or imposed body bending, entrains the motor CPG activity (9, 10). In limbed animals, rapid phasic feedback from mechanoreceptors tunes the rhythmic firing of motor neurons during step cycles (11–13). Mice lacking Piezo2, a mechanically activated channel expressed in proprioceptive neurons, exhibit severely uncoordinated body movement (14).

Descending signals, typically the projections of glutamatergic interneurons from the brain to the spinal or nerve cords, regulate both spinal CPG activities and motor patterns (15). In fish and rodent, descending reticulospinal neurons, arising from the brainstem and innervating excitatory spinal interneurons, can initiate locomotion and modulate speed (16–19), whereas those that activate inhibitory spinal interneurons can terminate locomotion (20). Descending interneurons that directly target the forelimb motor neurons are critical for skillful motor behaviors (21). In leech, activation of a descending command interneuron, cell 204, can initiate and maintain swimming (7, 22).

A deep understanding of the motor circuit must integrate local CPG elements, sensory feedback, and global command signals, to predict behavioral dynamics that result from the interaction of individual circuit components (23, 24). With a connectome at synaptic resolution and fully identified cell types (25, 26), Caenorhabditis elegans offers an opportunity to obtain a system-level understanding of a locomotor circuit.

The C. elegans ventral nerve cord consists of a network of excitatory cholinergic motor neurons, including the A and B types that execute backward and forward movement, respectively, and the inhibitory motor neurons (D type) that are innervated by the excitatory motor neurons (27). The AVB premotor interneurons, which receive inputs from many sensory neurons and interneurons, extend processes along the entire ventral nerve cord and exclusively form gap junctions with the B-type motor neurons (26, 28, 29) (illustrated in Fig. L1). The AVB premotor interneurons are required for forward locomotion (30); the precise function of their electrical synapses with B-type motor neurons, however, is not well understood.

Converging principles govern coordinated locomotion.
We undertook an integrative approach to address the circuit logic underlying forward locomotion in *C. elegans*, with an emphasis on how descending signals modulate the motor circuit dynamics. Descending inputs in other systems have been implicated in driving or modulating the activity of locomotor CPGs (16–18). Combining molecular genetics, optical manipulation of neuronal activity, and calcium imaging, we demonstrated that midbody B-type motor neurons could function as oscillators. AVB-B gap junctions drive the bifurcation of the B-type neuron dynamics from stationary to rhythmic activity, which promotes body bending during forward movement.

To generate coherent body undulation, motor neuron activities were entrained by proprioceptive feedback. Previously, we demonstrated the proprioceptive property of the B-type motor neurons in the mid and posterior body segments; such a property supports proprioceptive coupling between these B-type motor neurons and contributes to directional propagation of rhythmic body bending (31, 32). Combining experimental and computational analyses, we suggest that descending signals from AVB function synergistically with proprioceptive couplings to facilitate sequential activation of B-type motor neurons, allowing body bending to propagate directionally and efficiently to drive forward locomotion.

**Results**

**Gap Junctions Between AVB Premotor Interneurons and B-Type Motor Neurons Facilitate Bending Wave Propagation During Forward Locomotion.** The AVB premotor interneurons and B-type motor neurons form heterotypic gap junctions via the UNC-7 innexin (in AVB) and UNC-9 innexin (in B-type motor neurons) (Fig. 1A) (28, 29). To determine whether AVB-B gap junctions play a role in forward locomotion, we first examined the motor behaviors of *unc-7(*hp121) and *unc-9(*fc16) null mutants immersed in viscous solution (1 Pa s viscosity). In these gap junction-deficient mutants, the intrinsically higher levels of activity in the A-type motor neurons, which control backward locomotion, prevent animals from generating continuous forward movement (29). To reduce interference from motor activity arising from the backward motor circuit, A-type motor neurons were constitutively silenced by an ectopically expressed K$_{+}$ channel [*unc-4(*fc16)] (29) in examined strains (Table S1) and subsequent experiments.

We visualized and quantified *C. elegans* locomotion kinematics by curvature kymographs (Fig. 1B). During bouts of forward movement, each body segment alternated between positive (red)
and negative (blue) curvature, and the stripes of curvature propagated from the head to the tail. Coordinates along the worm body were defined as head = 0 and tail = 1 (Fig. 1B). In control animals (wild type with A-type motor neurons constitutively silenced), the bending amplitude was highest near the head, and then declined gradually and plateaued at the midbody (~40% of the body length, Fig. 1C). Both unc-7 and unc-9 mutants exhibited identical phenotypes: their bending amplitudes diminished monotonically from the head toward the tail (Fig. 1B and D and Movie S1).

UNC-7 and UNC-9 are expressed by many neurons besides the AVB and B-type neurons (28, 33). We found that the disruption of AVB-B gap junctions was responsible for the monotonic decline of forward-driving bending amplitudes in unc-7 and unc-9 mutants. First, when AVB premotor interneurons were optogenetically ablated using a mini-singlet oxygen generator (miniSOG) (34) [by either Pglg-55(B)::TOMM20-miniSOG or Ppara-11:PH-miniSOG], we observed the same trend of bending amplitude decline toward the tail (Fig. 1B and D and Fig. S1). Second, restoring innexin UNC-7 in AVB (unc-7; Ppara-11::UNC-7) in unc-7 mutants was sufficient to restore the plateau phase of bending amplitude (Fig. 1C and D and Movie S3). We also noticed that the frequency of undulatory waves (Fig. 1B and Fig. S1A) was significantly reduced in unc-7, unc-9 mutants, and AVB-ablated animals. The current study focused on bending amplitude propagation.

Linear Model Predicts Deteriorated Undulatory Wave in the Presence of AVB-B Gap Juncions. How do AVB-B gap junctions promote efficient body bending propagation toward the tail? Previously, we showed that worm undulation during forward locomotion involves local and directional proprioceptive coupling between adjacent body regions (31). Curvature change in a body region, induced by a pneumatic microfluidic device, activates bend-sensitive B-type neurons and defines the curvature of the posterior neighbor (31). Consistently, when we trapped the middle body region of a wild-type worm in a static channel with defined curvature, the unrestrained posterior body region exhibited bending curvature in the same direction as that imposed by the microfluidic channel (Fig. 2A and B and ref. 31).

A simple possibility is that proprioceptive coupling is UNC-7- and UNC-9-dependent. To test this possibility, we examined unc-7 and unc-9 mutants constrained by microfluidic channels. Consistent with a previous finding (31) and as observed for control animals, their posterior body regions still followed the curvature imposed on the anterior regions (Fig. 2B and C and Fig. S2). Therefore, proprioceptive coupling remains largely intact in the absence of UNC-7- or UNC-9-dependent gap junctions.

We next took a theoretic approach to probe how AVB-B gap junctions might affect bending wave propagation. We first adopted a linear model (31), where we asserted that undulatory waves start with rhythmic dorsal-ventral alternative bends near the head; directional proprioceptive coupling between adjacent body regions is fully described by the following first-order differential equations:

\[
\begin{align*}
\frac{dC_m v_i}{dt} &= g_m (-v_i + c_{k_{i-1}}) - g_i (v_i - v_{AVB}) \\
\frac{dU_i}{dt} &= -U_i + v_i \\
\tau_n \frac{dK_i}{dt} &= -k_i + d_{max} * U_i / b \\
\end{align*}
\]

We divided the worm into six segments, with subscript i as the segment number. In the first equation, \(v\) describes relative motor neuron activity: when dorsal B-type neurons have a higher activity than ventral ones, \(v > 0\), and vice versa. \(k_i\) is the curvature of a given segment, and \(c_{k_{i-1}}\) describes the proprioceptive signal from the neighboring anterior body segment, where \(c > 0\) is the coupling strength. \(C_m\) is the membrane capacitance and \(g_m\) the leaky conductance. The term \(-g_i (v_i - v_{AVB})\) describes the contribution from AVB-B electrical coupling, where \(g\) is the gap junction conductance. Here, we set AVB membrane potential at a constant depolarized value, which is consistent with experimental observations that AVB exhibit elevated yet nonsessile calcium activity during forward locomotion (29, 35, 36). In Eq. 1, for simplicity, we set \(v_{AVB} = 0\) to eliminate the bias of \(v\). A more detailed model that treats dorsal and ventral motor neuron activities separately is described in Supporting Information.

The second equation relates motor neuron activity to muscle torque: \(u\) is a dimensionless variable and \(d_{max} * u\) is the maximum torque that the muscle cells can generate. The last equation describes how the segment curvature changes with muscle torque: \(b\) is the bending modulus of the body and \(\tau_n\) is a time constant (31). Published work (31, 37, 38) has established that when C. elegans swim in viscous solution (our experimental condition), the biomechanics of the worm body can be modeled as elastic rod bent in viscous medium at low Reynolds number, and the inertia can be ignored. If we consider sinusoidal dynamics of curvature and torque, the time constant \(\tau_n\) has the following expression (31, 37):

\[
\tau_n = C_N / b \left(2\pi / \lambda\right)^4 \approx 30\eta / b \left(2\pi / \lambda\right)^4,
\]

Fig. 2. UNC-7- and UNC-9-dependent gap junctions are not required for proprioceptive couplings in the forward motor circuit. (A) Schematics of the microfluidic device for constraining a body segment with defined curvature. (B) Time-lapse video images of control (Upper), unc-7 (Middle), and B-type neurons ablated (Lower) worms trapped in the microfluidic device. In both control and unc-7 mutant animals, the posterior unrestrained body region followed the curvature of the channel. However, this was not the case when B-type motor neurons were optogenetically ablated. (C) In AVB-B gap junction-deficient mutants, or AVB-ablated worms, the posterior unrestrained body region also followed the curvature of the channel. Boxes indicate Q1 to Q3, error bars represent Q1 – 1.5IQR and Q3 + 1.5IQR, respectively, and notches indicate 95% confidence interval. ***p < 0.0001, compared with other strains, by Mann–Whitney U test. Control [N2; Punc-4:TWK-18(gf)], n = 40 measurements, 8 worms; unc-7 [unc-7; Punc-4:TWK-18(gf)], n = 41 measurements, 12 worms; unc-9 [unc-9; Punc-4:TWK-18(gf)], n = 38 measurements, 9 worms; AVB-ablated [Pglg-55(B)::miniSOG], n = 60 measurements, 10 worms; B-ablated [Pacr-5::minSOG], n = 33 measurements, 9 worms. (D) In the linear model, incorporating the AVB-B gap junction inputs further deteriorated bending wave propagation.
where \( C_y \) is the drag coefficient perpendicular to the worm body, a parameter that is proportional to the viscosity of medium \( \eta \), and \( \lambda \) is the spatial wavelength of undulation.

Simulation of the linear model predicted an exponential decay of bending amplitude toward the tail (Fig. 2D). By considering a continuous form of local coupling (Supporting Information), we solved the linear model analytically and identified a self-consistent solution for the spatiotemporal profile of the body curvature:

\[
k(x,t) = k_0 \exp(-x/\xi) \exp \left( \frac{2\pi}{\lambda} - i\alpha t + \phi(x) \right),
\]

where \( \omega \) describes the angular frequency; \( \phi(x) \) is a phase lag term, and \( \xi \) is the decay length constant, which, to the leading order, is given by the following:

\[
\xi \approx \frac{l}{1 - ca_{\max}/b}, \quad \text{subject to } \frac{ca_{\max}}{b} \leq 1,
\]

where \( l \) is the spatial scale for local proprioceptive coupling (31). \( \xi \to +\infty \) leads to identical bending amplitude along the body. Incorporation of AVB-B electrical coupling effectively changes \( c \) to \( c_{\text{AVB}}/(c_{\text{AVB}} + g) \). This prefactor further reduces the length constant.

Therefore, in a linear coupling model where the B-type motor neurons are passive recipients of proprioceptive inputs, opposite to our experimental findings, gap junctions between AVB and B-type neurons would further deteriorate the bending wave propagation (Fig. 2D).

**B-Type Motor Neurons Are Nonlinear Functional Units.** The discrepancy between the theoretical model and experimental observations indicates that some basic assumption in the linear model must be modified. We hypothesized that proprioceptive signals may couple nonlinear functional units within adjacent regions. Oscillation is a common form of nonlinearity. We thus tested whether CPGs exist along the worm nerve cord.

Our linear coupling model predicted that abolishing head bending activity would abolish the undulatory wave; a coupled-CPG model (39), however, predicts the opposite. To distinguish these possibilities, we performed selective optogenetic inhibition of B-type motor neurons in a defined anterior body region (0.1–0.3 along worm coordinates) of a freely swimming animal (Pacr-5::Arch) (Fig. 3 A and B and Movie S2). Upon green light illumination, we effectively abolished bending near the head region (Fig. 3B, curvature kymograph). In the absence of local proprioceptive signal from adjacent anterior body region, the midbody (~50% of the body length), however, continued to generate rhythmic bending with increased undulation frequency and reduced amplitude (Fig. 3 B and E and Movie S2). When a worm swam in 1 Pa·s viscous solution, the undulation frequency was ~0.8 Hz (Fig. 3C); when anterior bending activity was optogenetically inhibited, the midbody undulation frequency doubled (~1.6 Hz, Fig. 3C). We observed a similar phenomenon when anterior undulation was abolished optogenetically, either by inhibiting both the A-type and B-type motor neurons (Pacr-2::Arch, Fig. S34), or by directly inhibiting anterior muscle cells (Pmyo-3::NpHR, Fig. S34).

![Fig. 3](image-url)

**Fig. 3.** Midbody B-type motor neurons generate rhythmic activity independent of proprioceptive coupling. (A) Time-lapse video images from a recording when B-type motor neurons in an anterior body region (10–30% along the worm body) were optogenetically inhibited. (B, Upper) Schematic illustrates the effect of spatially selective inhibition of B-type motor neurons. Optogenetic inhibition of anterior B-type motor neurons induced high-frequency undulation in the posterior region. (Lower) Representative curvature kymograph. Green shaded region shows the selected spatiotemporal region for optogenetic inhibition. (C) *C. elegans* undulation frequency at different viscosity. Black line is undulation frequency of control animals; blue line is midbody undulation frequency when anterior bending activity was abolished. Error bars are SEM; \( n \geq 8 \) worms for each data point. (D) Representative curvature kymograph during optogenetic inhibition of anterior B-type motor neurons, with and without midbody B-type neurons (DB 4-5 and VB 5-7). (E) Pie chart summarizes the percentage of locomotor states when anterior bending activity was abolished. \( h-f \) wiggle: midbody undulation frequency was higher than that before anterior bending activity was abolished; non-\( h-f \) wiggle: midbody undulation frequency was equal to or less than that before anterior bending activity was abolished; paralysis: no waves emerged in the midbody. Control (Pacr-5::Arch), \( n = 241 \) measurements, 20 worms; midbody B-type neuron-ablated worms (Pacr-5::Arch; Pacr-5::miniSOG), \( n = 77 \) measurements, 11 worms.
These observations favor the possibility that at least some B-type motor neurons are intrinsic oscillators. Whereas the normal undulation frequency decreased in more viscous solution (Fig. 3C and ref. 37), the midbody undulation frequency remained fixed across a wide range of viscosities (<1 Pa·s) when anterior bending activity was abolished (Fig. 3C and Fig. S3B). The frequency of the midbody oscillators, which could be entrained by head bending, appeared to only weakly depend on the mechanical load of the environment.

To determine whether the B-type motor neurons were responsible for generating midbody oscillation, we performed systematic ablation of B-type neurons (Pacr-5::minSOG) in the ventral nerve cord. Ablating a cluster of midbody B-type motor neurons (DB4-5 and VB5-7) abolished high-frequency oscillation when anterior bending activity was abolished (Fig. 3D and E). When only a subset of neurons in this cluster was ablated, the high-frequency midbody undulation could still be induced (Fig. S34). In these animals, we occasionally observed independent bending waves generated by the head and posterior body regions, respectively (Fig. S3C). When the activity of other ventral cord motor neurons was blocked, either by silencing the A-type motor neurons (Punc-4::TWK-18, Fig. 4B, control) or by eliminating inhibitory neurotransmitter release (Fig. S34), B-motor neuron-dependent midbody undulation persisted. These data, together with the observation that the midbody undulated in the absence of proprioceptive signal arising from the adjacent anterior region (Fig. 3D and E), strongly suggest that these B-type motor neurons do not passively respond to proprioceptive signals. They instead function as nonlinear units that resemble CPG modules distributed along the body.

**AVB-B Gap Junctions Drive Bifurcation of B-Type Motor Neuron Dynamics.** We next asked whether AVB-B gap junctions play a role in high-frequency midbody undulation when the anterior bending activity is abolished. In AVB-B gap junction-deficient mutants (unc-7 and unc-9), as well as AVB-ablated animals, optogenetic inhibition of anterior bending no longer induced midbody undulation (Fig. 4A and B). Instead, optogenetic inhibition of either the anterior B-type motor neurons, or anterior body wall muscles led to paralysis of the entire body (Fig. 4A and B). Restoring UNC-7 inactivin expression in several interneurons including AVB (unc-7; Pare-11::UNC-7) significantly increased the efficacy for inducing high-frequency midbody undulation (Fig. 4B and Movie S3). These results suggest that AVB interneurons and their gap junction couplings with the B-type motor neurons are required for inducing midbody high-frequency undulation. Consistently, optogenetic activation of several interneurons that include AVB (Pare-11::Chrimson) triggered forward locomotion from either the pause state or the backward movement (Fig. 4C and Movie S7), whereas their optogenetic inhibition (Pare-11::GtACR2) (40) reliably halted forward locomotion (Fig. 4D and Movie S8).

To directly investigate whether B-type motor neurons could generate rhythmic activities in the presence of AVB gap junction inputs, we performed calcium imaging of B-type motor neurons in unc-13(e51), a mutation that largely eliminates chemical synaptic transmission of all neurons, whereas the electrical synapses persist. In the absence of AVB activation (control in Fig. 5A), B-type motor neurons did not exhibit rhythmic calcium activities. Upon optogenetic activation of AVB (Pare-11::Chrimson), B-type motor neurons in the midbody region exhibited rhythmic calcium activities (Fig. 4E and F and Fig. S4).

Given that AVB calcium activities are nonosscillatory (29, 35, 36), our data suggest that AVB-B gap junctions drive bifurcation of B-type motor neuron dynamics, leading to a transition from the stationary to oscillatory state. We propose a model where in the presence of AVB-B gap junctions, time-varying proprioceptive signals from the anterior body may easily induce changes in B-type motor neuron membrane potential, thus facilitating bending wave propagation.

A **Nonlinear Model Recapitulates AVB-B Gap Junction-Dependent Bifurcation of B-Type Motor Neuron Dynamics.** We next sought theoretical verification of our functional model. For simplicity, we developed a phenomenological model based on active Ca\(^{2+}\) and K\(^+\) conductance (41), in which the dynamics of dorsal and ventral motor neurons within a given body segment are governed by the following equations:

\[
\begin{align*}
C_m \frac{dV_d}{dt} &= -g_L(V_d - E_L) - g_{Ca}m_n(V_d) \cdot (V_d - E_{Ca}) \\
&\quad - g_{K}n_d \cdot (V_d - E_K) + c_k \cdot v_{11} + g(V_{AVB} - V_d), \\
\tau_m \frac{d}{dt} n_d &= -n_d + \alpha (V_d), \\
C_m \frac{dV_i}{dt} &= -g_L(V_i - E_L) - g_{Ca}m_n(V_i) \cdot (V_i - E_{Ca}) \\
&\quad - g_{K}n_i \cdot (V_i - E_K) + c_k \cdot v_{11} + g(V_{AVB} - V_i), \\
\tau_m \frac{d}{dt} n_i &= -n_i + \alpha (V_i).
\end{align*}
\]

In Eq. 5, \(V\) is motor neuron membrane potential; subscripts \(d\) and \(v\) denote dorsal and ventral sides, respectively; \(m\) and \(n\) are voltage-dependent Ca\(^{2+}\) and K\(^+\) activation variables, respectively. Parameter values in this equation were chosen (Supporting Information) to accommodate the following experimental findings. First, when the head and body undulations are decoupled (\(c_k \approx 0\)), gap junctions between AVB interneurons and B-type motor neurons induce motor neuron oscillation (Fig. 5A). Second, proprioceptive signals arising from head bending entrain posterior motor neuron oscillation (Fig. 5A). The nullcline analysis, which allows for visualization of the dynamical variables on a vector field, provides useful information on the transition from the resting state to the limit cycle in the presence of AVB-B gap junctions (Fig. 5B). Furthermore, simulation recapitulated the experimental finding that AVB-B gap junctions help equalize bending amplitude along the body (Fig. 5C).

**Electrical Couplings Between Motor Neurons and AVB-B Gap Junctions Permit Rapid and Reciprocal Interactions Between Head and Body Motor Activities.** Having considered the functions of the descending interneuron inputs to B-type motor neurons, we next asked whether local gap junctions between motor neurons (Fig. 1L), which were suggested by electron microscopy analyses (25, 26), play roles in forward locomotion.

This question arises from the observation that optogenetic inhibition of B-type motor neurons in middle or posterior body regions, unlike the case of inhibiting the anterior body region, induced rapid (within ~300 ms) paralysis of the whole worm with the maximum laser intensity (Fig. 6A and B, Fig. S6, and Movie S4). Electrical coupling is the best candidate for rapid redistribution of a hyperpolarization current among B-type motor neurons (Pacr-5::Arch). In both unc-7 mutants and AVB-ablated worms, whole-body paralysis could still be induced upon silencing midbody and posterior B-type motor neurons (Fig. 6C), using the maximum laser intensity, suggesting that the hyperpolarization signal could still be transduced in the absence of AVB-B gap junctions.

In unc-9 mutants, however, rhythmic bending in the anterior body persisted when midbody B-type motor neurons were silenced (Fig. 6A and C and Movie S5). Restoring UNC-9 expression in cholinergic motor neurons, including the B- and A-type motor neurons (Pacr-2::UNC-9), restored the ability to optogenetically induce whole-body paralysis (Fig. 6C). Therefore, electrical couplings among motor neurons may contribute to the paralytic effect.

Xu et al.
Fig. 4. AVB-B electrical coupling drives the bifurcation in the B-type neuron dynamics. (A) Representative curvature kymographs in AVB-B gap junction-deficient or AVB-ablated worms when anterior bending activity was abolished. (B) Probability for triggering high-frequency mid-body undulation when anterior bending activity was abolished. Pie chart summarizes the percentage of worm locomotor states. Error bars indicate 95% binomial proportion confidence interval. ***P < 0.0001, *P = 0.002, *P < 0.0001 (*compared with Ctrl, *compared with UNC-7 rescued in AVB), χ² test. Strains for comparisons are as follows: control [Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 113 measurements, 13 worms; unc-7 [unc-7(hp121); Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 102 measurements, 21 worms; unc-9 [unc-9(fc10); Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 116 measurements, 26 worms; AVB-ablated [Pgc-55::Chrimson; Pacr-5::Arch], n = 40 measurements, 11 worms; UNC-7 rescued in AVB [unc-7(hp121); Pacr-5::Arch; Punc-4::TWK-18(gf); Pacr-11::UNC-7], n = 86 measurements, 12 worms. (C) Optogenetic activation of AVB premotor interneurons could trigger forward locomotion. (Left) Optogenetic activation (Pacr-11::Chrimson, n = 133 measurements, 11 worms), showing locomotion velocity with time; red light (635 nm, 12 mW/mm²) was turned on at t = 0. Gray traces represent individual trials, and shaded region represents SEM. (Right) Probability for triggering forward locomotion. Ctrl represents worms without feeding ATR. Error bars indicate 95% binomial proportion confidence interval; ***P < 0.0001, χ² test. (E) Example traces of calcium dynamics of B-type motor neurons. Darker lines were smoothed data, using an exponential filter to reduce high-frequency noise. Upon light illumination that activated AVB interneurons, neighboring VB/DB motor neuron exhibited oscillatory yet anticorrelated calcium activities. To eliminate the proprioceptive coupling signal, we restrained the worm body region anterior to the imaging cells within a straight microfluidic channel. (F) Power spectral density of calcium dynamics using the smoothed data.
The efficacy for optogenetically inducing whole-body paralysis, however, was dose dependent. When the midbody B-type motor neurons were inactivated at lower laser intensity, which likely reduced the degree of hyperpolarization, forward locomotion was not abolished. Instead, both undulation amplitude and locomotor speed were reduced (Fig. 6 D and E). Interestingly, in the absence of AVB interneurons, a higher laser intensity was required to modify the locomotor kinematics, and to induce whole worm paralysis (Fig. 6 D and E). These results suggest a potential mechanism by which gap junctions between motor neurons and AVB-B gap junctions function together to retrogradely regulate head bending activity, and hence reconfigure the dynamics of worm body undulation.

Discussion

Electrical synapses are not only prevalent in invertebrate motor circuits, but also present in developing and mature vertebrate spinal cords (42–44). The functional implications of gap junctions in motor circuits and motor behaviors could be counterintuitive, confounding, and are often underappreciated (45, 46). In the mature zebrafish spinal cord, electrical couplings between motor neurons and premotor interneurons point to a potentially nimble feedback mechanism for modulating rhythmic activity (47). Experiments and modeling of crustacean stomatogastric ganglia suggest that the interplay between electrical and chemical synapses provides degenerate circuit mechanisms for switching between fast and slow oscillatory behaviors (48).

In the C. elegans motor circuit, the A-type motor neurons function as oscillators for reversal movements, and the descending AVA interneurons regulate their activities through a mixed gap junction and chemical synapse configuration (29, 49). At rest, AVA-A gap junctions shunt A-type motor neurons’ intrinsic oscillatory activity so that a bias toward forward movement can be established (29, 49). Upon stimulation, the AVA interneurons potentiate A-type motor neuron oscillation mainly through chemical synaptic inputs (49), as well as gap junction-dependent antidromic rectification (50) that prolongs reversal movements.

In the motor circuit that drives C. elegans forward movement, we discovered that AVB-B electrical couplings induced oscillations in midbody B-type motor neurons and facilitated undulatory wave propagation. To better understand how descending inputs drove the bifurcation of motor neuron dynamics, we developed a nonlinear dynamic model based on voltage-dependent conductance. Detailed characterization of the intrinsic membrane conductance and experimental test of our model required electrophysiological recordings in motor neurons, a difficult technique that has only recently become possible (50). Intriguingly, a complementary study of the C. elegans reversal motor circuit found that P/Q/N-type voltage-dependent Ca^{2+} channels were required for generating intrinsic, oscillatory activity in the A-type motor neurons (49). Whether the same channels drive B-type motor neuron oscillation will be addressed in future studies.

Coordinated movement in larger animals involves networks of CPGs that are coupled through mechanosensory feedback (5). In leech, stretch-sensitive feedback can alter the intersegmental phase lags between CPGs (10, 51). During stick insect walking, proprioceptive feedback can entrain the motor patterns that drive individual joints, leading to interjoint coordination (13). Specific classes of mechanosensory neurons in fly larvae are required for efficient propagation of peristaltic waves (52, 53).

Here, our data indicate that distributed oscillators for forward movement, operated by at least some B-type motor neurons, exist in the C. elegans ventral nerve cord. Because worms must adapt to extreme ranges of external mechanical loads imposed by a changing environment (37), directional proprioceptive signals, also transduced by B-type motor neurons (31), are essential for entraining the rhythm of body oscillators, and for propagating coherent bending waves from the head to the tail (Fig. 7). In a linear coupling model where motor neurons passively respond to proprioceptive inputs, bending amplitude would suffer an exponential decay toward the tail. Our experimental finding and theoretical analysis thus provide insight into the interplay between sensory feedback and oscillators within the motor circuit.

We also found a previously unknown role of electrical couplings between motor neurons, which permits rapid and reciprocal interaction between the head and body motor activities (Figs. 6 and 7). Overexpression of UNC-9 in the B-type motor neurons led to constitutive paralysis (Movie S6); we suspect that strong electrical couplings between motor neurons tend to synchronize motor activity along the whole body, thus deteriorating bending wave propagation. Weak electrical couplings between motor neurons, on the other hand, may facilitate head bending activity and augment the excitability of motor neurons along the body. Direct testing of the functional contribution of local electrical couplings requires the elimination of electrical synapses between motor neurons, while sparing the AVB-B ones.
Fig. 6. Electrical coupling among motor neurons and AVB-B gap junctions allows for rapid and reciprocal interactions between head and body motor activities. (A) Comparison of representative curvature kymographs of control [Pacr-5::Arch; Punc-4::TWK-18(gf)] and unc-9 mutant [unc-9(fc16); Pacr-5::Arch; Punc-4::TWK-18(gf)] worms during optogenetic inhibition of midbody B-type motor neurons. Green shaded regions are selected regions (0.4–0.6 fractional distance) subjected to 0- to 7-s stimulation by the green laser. (B) Delay time between the onset of green laser and changes in bending. Error bars are SEM (also see Fig. S6). (C) Quantification of the whole-body paralytic effect during optogenetic inhibition of midbody B-type motor neurons. Red crosses are outliers, red lines are medians, red dots are means, error bars represent Q1 – 1.5IQR and Q3 + 1.5IQR, respectively, and notches indicate 95% confidence interval. In unc-9 mutants, the boundary shifted toward the midbody, reflecting that the anterior body could still undulate. ***P < 0.0001, Mann–Whitney U test. Control [Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 70 measurements, 17 worms; unc-7 [unc-7(hp121)]; Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 43 measurements, 11 worms; unc-9 [unc-9(fc16); Pacr-5::Arch; Punc-4::TWK-18(gf)], n = 59 measurements, 17 worms; AVB-ablated (Plgc-55::miniSOG, Pacr-5::Arch), n = 65 measurements, 18 worms; UNC-9 rescued in the B-type and A-type motor neurons [unc-9(fc16); Pacr-5::Arch; Pacr-2:UNC-9], n = 48 measurements, 9 worms. (D) Laser intensity-dependent effects on the bending amplitude along the body. Error bars are SEM. (E) Laser intensity-dependent effects on efficacy for inducing whole-body paralysis, locomotion speed and mean amplitude decreases along the body [0.2, 0.7]. Error bars (speed and amplitude) are SEM; error bars (paralysis) are 95% binomial proportion confidence intervals. n ≥ 42 measurements, ≥6 worms for each data point. Maximum laser intensity, 16 mW/mm².
Current genetic tools for manipulating gap junction expression with defined wiring specificity remain to be developed because both types of gap junctions require UNC-9 innexin. UNC-9 is also expressed by the body wall muscle cells (54). Could electrical couplings between muscle cells and those between motor neurons have similar functions? We (and others) found that optogenetic inhibition of midbody muscle cells did not affect bending activity in the anterior body, but did abolish bending activity in the posterior body (55). This effect is consistent with our proprioceptive coupling model (Fig. 7). Furthermore, in unc-13 mutants, where all chemical synaptic inputs from motor neurons to muscles are eliminated, targeted optogenetic activation of ventral or dorsal muscle cells induces local body bending, not bending in neighboring regions (31). These data suggest that any electrical coupling between body wall muscle cells only plays a restricted role for *C. elegans* body bend propagation.

Despite substantial anatomical differences between the worm motor circuit and those in higher organisms, we identified converging principles that govern coordinated locomotion. By integrating global descending signals, biomechanical feedback, and neuromuscular dynamics, our findings and models represent a key step toward a full system model of animal locomotion.

**Methods**

**Worm Strains and Cultivation.** Wild-type (N2), mutant, and transgenic worms were cultivated using standard methods (58). Strain information can be found in Table S1. Transgenic worms used in all optogenetic experiments were cultivated in the dark at 20–25 °C on NGM plates with *Escherichia coli* OP50 and all-trans retinal (ATR). We performed all experiments using young adult hermaphrodites.

**Microfluidic Device.** Custom microfluidic devices were fabricated in polydimethylsiloxane using soft lithography. We loaded each microfluidic channel with dextran in M9 buffer (in most cases), sandwiched between two glass slides, and retained within the field of view of an imaging objective by a custom tracking system. Video sequences were taken by a Basler CMOS camera (aca2000-340km), and the worm body centerline was extracted in real time. We used MATLAB custom software (MathWorks) for postprocessing behavioral data. We used the ColBeRT system (55) to perform spatially selective optogenetic manipulation for different motor circuit components. For optogenetic inhibition, we used a 561-nm solid-state laser with maximum intensity at 16 mW/mm² (Arch) or a 473-nm solid-state laser at 0.76 mW/mm² (GTACR2).

**Calcium Imaging and Optogenetic Stimulation.** We imaged the B-type motor neuron unc-13 mutants using wide-field fluorescent microscopy. Anterior body region of a single young adult worm was restrained in a straight microfluidic channel; middle and posterior body regions were freely immersed in liquid solution (5% dextran), hps548, an integrated calcium reporter transgene that expresses the GCaMP6s::wCherry fusion protein in the B-type motor neurons, was excited by blue and yellow light. Green and red fluorescence emission signals were collected through a Nikon Plan Apo 12× objective and a high-sensitivity camera (Andor iXon 897) and projected simultaneously onto one-half of a CMOS sensor. Calcium imaging and optogenetic stimulation of head interneurons including AVB (green light) were synchronized. Worms without feeding ATR were used as control, while other experimental conditions remained identical.

**Note.** Two related works [Gao et al. (49) and Fouad et al. (58)] on the backward and forward motor circuit of *C. elegans* were in print when this work was under review. An earlier version of this work can be found at https://www.biorxiv.org/content/early/2017/06/18/131490.

**ACKNOWLEDGMENTS.** We thank Christopher Fang-Yen and Anthony Fouad for discussions. We also thank two anonymous reviewers for their critical comments.
